## GLOSSARY

- affiliative behavior** Behavior that is supportive and brings individuals together.
- agonistic behavior** Behavior that is aggressive, threatening, combative, and submissive.
- altruism** Behavior that enhances the recipient's reproduction while reducing the actor's.
- musth** Annual reproductive period in male elephants characterized by extreme aggressiveness and secretions from temporal glands.
- polyandry** Mating system in which a female mates with more than one male.
- polygyny** Mating system in which a male mates with more than one female.
- protandry** Breeding system in which individuals change sex from male to female.
- protogyny** Breeding system in which individuals change sex from female to male.
- 

**SOCIAL BEHAVIOR** characterizes the interactions that occur among individuals. These can be aggressive, mu-

tualistic, cooperative, altruistic, and parental. When individuals interact repeatedly, social relationships develop and these can form among strangers, relatives, members of the same or opposite sex, and members of the same or different generations. Sets of consistent social relationships produce social systems or social organizations that can be variations on monogamous or polygamous themes and involve various types of helpers. The nature of any social system is ultimately determined by ecological and social circumstances, demography, and kinship.

## I. INTRODUCTION

No animals are completely asocial. All must come together at some point to breed. Few, however, are highly social coming together and interacting repeatedly. For those that do, social interactions—both affiliative and agonistic—occur sometimes with relatives, sometimes with strangers, sometimes with members of the same sex, sometimes with members of the other sex; and sometimes with members of the same generation while at other times with members of other generations. The interactions themselves can be aggressive, cooperative, or even altruistic and can develop into strong relationships among particular individuals. Depending on the nature of these relationships and with whom they form, a variety of social systems can develop. Some may be made up mostly of kin or mostly of nonkin, some may be based on territorial separation or on the aggregation

of competitors, some will exhibit monogamous as opposed to polygamous relationships between the sexes, and some will rely on the help of nonmates in the rearing of offspring. This seemingly bewildering pattern of social diversity is shaped ultimately by ecological circumstances and patterns of demography. But the very nature of a population's social structure itself will in turn affect the population's demography and its place in the biological community. It is these dual connections between social activities and the environment and the resulting feedbacks that mandates understanding both the causes and consequences of animal sociality so that effective and efficient management or conservation policies can be developed for protecting endangered species and for preserving biodiversity and ecosystem integrity.

## II. FROM SOCIAL BEHAVIOR TO SOCIAL ORGANIZATION: PATTERNS AND MECHANISMS OF FORMATION

Social animals form groups. While some are temporary, others are more permanent. Given that animals in groups incur automatic costs of increased disease and parasite transmission as well as intensified competition, groups will only form when there are sufficiently large benefits to offset these costs. Benefits largely come in three forms. First, animals can develop forms of social behavior specific to stable groups that compensate them for the costs of group living. One such example is forming mutual grooming partnerships as do olive baboons (*Papio anubis*) to lower disease and parasite transmission. Second, by forming groups animals can enhance foraging by being better able to find, acquire, or defend food. Examples include colonial cliff swallows (*Hirundo pyrrhonota*) that transfer information about the locations of rich but ephemeral feeding sites or troops of monkeys who drive smaller troops away from feeding trees. And third, animals in groups can reduce their risk of being preyed upon by either increasing the likelihood of detecting predators, diluting their personal risks, or by decreasing the likelihood that predators can make a kill; confusion and cooperative defense are mechanisms that provide such antipredator benefits. Examples include the scattering of fish in schools, or the gathering of young inside a ring of adult musk oxen (*Ovibos moschatus*) facing outwards toward approaching predators with upturned horns.

Depending on the nature of the social relationships that develop, groups take on particular organizational

forms. As Fig. 1 illustrates, these relationships are shaped by the features of an individual's physical and social environment. Particular distributions of food, water (bottom-up factors) and predators (top-down factors), in conjunction with the physiological demands of individuals differing in body sizes or reproductive states, will determine the frequency and magnitude of competitive and cooperative interactions that occur. The outcome of these repeated interactions will shape overall time budgets and activity patterns. Because females maximize their reproductive success relative to other females by their ability to raise offspring to the age of independence, females are forced to efficiently solve the three ecological problems listed earlier. What particular associations and distributions develop will depend on the particular ecological and physiological circumstances that females experience. These associations and distributions in turn will shape male associations and distributions, because male fitness is mostly determined by their ability to acquire mating access to disproportionate numbers of females. The mating

system that develops becomes the core of a species' social system.

### A. Ecological Challenges and Phenotypic Constraints

Typically, in environments in which resources are abundant, especially when they are evenly distributed, competition is low enough to permit females to aggregate. If sufficiently large foraging or antipredator benefits can be derived by females that aggregate, and the groups that form are not too large, then these groups can be defended by single males and so-called harem defense polygyny results. If resources, however, are more patchily distributed so that competition among females intensifies periodically, then female group sizes will vary and female associations become more transitory. Rather than defending unstable groups of females, males instead attempt to defend resource patches sought by females. Typically, in these systems of "resource defense polygyny" the most able males defend the best patches and thus gain access to the largest number of females for the longest periods of time. If resources are not only patchily distributed, but the patches are large, widely separated, and fluctuate seasonally in abundance, then competition among females becomes so low that the formation of large groups is even more likely, provided that females can range widely and follow the shifting locations of peaks in food abundance. Males will thus be forced either to follow these large groups competing for, and then tending, one reproductive female at a time ("wandering") or to position themselves at the intersection of female migratory routes and wait for females to visit them ("lekking"). In either case, intense male-male competition generates a mating system based on "male dominance polygyny," and in the latter case females are afforded the exquisite opportunity to simultaneously compare many males before choosing with which one to mate! Whenever resources are sparsely but somewhat evenly distributed, high levels of competition prevent females from forming groups. As a result, individual females defend territories thus ensuring a regular supply of a renewing resource. Since solitary individuals searching for members of the opposite sex will face increased predation risk, pairs often share territories and monogamy results.

This model accounts for the diversity of mating systems for many different groups of animals including insects, fish, reptiles, rodents, and many varieties of birds, ungulates, carnivores, marine mammals, and pri-

mates. One of the best illustrations showing how environmental forces interact with physiological constraints to shape a species' social system emerges from Peter Jarman's classic study of African antelopes. By showing how body size affected the ways in which different species perceived, and then responded to, the distribution and abundance of forage and predators of grasslands, Jarman showed why particular social systems increased survival and reproductive prospects for particular species. He argued that the smallest bodied species, such as did-dik (*Madoqua kirkii*), duikers (*Cephalophus* spp., *Sylvicapra* spp.), suni (*Neotragus moschatus*), and klipspringers (*Oreotragus oreotragus*) require limited amounts of high-quality vegetation. But given their small size, such food items often appear as if they are widely scattered. Faced with high levels of competition and intensified risks of predation, territoriality and monogamy appear to be the best strategies. Pairs generally live in wooded or shrub-rich areas where moisture enables vegetation to grow and renew itself well into the dry season. By signaling territorial ownership via scent rather than by means of sound or visual display these small-bodied species reduce the chances that any of a large number of carnivores will prey on them.

As species increase in body size, both physiologically determined dietary needs and the way acceptable forage becomes distributed on the landscape changes. Since "crypsis" becomes an untenable antipredator strategy for larger and more widely ranging species, forming groups becomes the best strategy for larger species to lower predation risk. Fortunately, with larger size also comes an ability to subsist on more abundant, lower-quality vegetation. When it is patchily distributed, as it is for impala (*Aepyceros melampus*), reedbuck (*Redunca* spp.), and some gazelles (*Gazella* spp.), males defend the best patches that females prefer. When the vegetation is more evenly distributed, which often results simply from the fact that larger species such as eland (*Taurotragus oryx*) and Cape buffalo (*Synceros caffer*) can utilize even the lowest quality items, larger groups form. Because the largest species view large continuous swards of a landscape as acceptable, competition is virtually eliminated and many males associate with many females. With such high levels of male-male competition, defense of a small subgroup of females becomes impossible and dominance defense systems develop.

The same sorts of connections between changing ecological circumstances shape the types of sociality exhibited in other taxa. A brief survey of mammals illustrates some of the more general patterns. For the

equids the close association between food and water enable horse (*Equus caballus*) and plains zebra (*Equus burchelli*) females of different reproductive states to associate permanently. Thus males are able to defend such groups and so-called harems form. When these two resources are widely dispersed, as for Grevy's zebra (*Equus grevyi*) and the Asiatic wild ass (*Equus hemionus*), females of different states are precluded by metabolic constraints from foraging together. As a result, males compete for territories along traveling routes that take females from feeding areas to watering points.

In felids, females remain separated when food is scarce and the habitats are densely wooded because in such circumstances individual prey can be caught and consumed before competitors can intervene. In more open habitats and where both prey and competitors are large and much more numerous, coalitions of females form to help hold on to kills until they are completely devoured. If these female coalitions are themselves large, then there is pressure for males to aggregate to control reproductive access to females. Thus the only highly social felid is the savanna-living lion (*Panthera leo*), yet even in this plentiful landscape the leopard (*Panthera pardus*) remains solitary because it can safely cache its large prey in trees.

For canids monogamy is the rule. But variations do occur with small-bodied foxes (*Vulpes* spp.) sometimes exhibiting polygyny and large-bodied hunting dogs (*Lycan pictus*) and timber wolves (*Canis lupus*) developing polyandry. Typically canids need help from nonbreeding foragers to help nourish lactating mothers. For the mid-sized jackals, such as the silverback jackal (*Canis mesomelas*), the helpers are young from previous litters that cannot themselves find successful breeding locations. For the smallest species, however, prepartum investment in young is relatively small for a female and thus her mate provides all the help that is needed. In years when prey resources are very high, competition between mothers and their soon-to-be-fecund daughters is low and their daughters are not forced to disperse. As a result they provide neighboring males with additional mating opportunities. For the largest bodied species, however, female prepartum investment is very high and they need all the help they can get. To enlist the support of other adult males that must hunt cooperatively to capture large prey, a dominant female not only kills the offspring of other females in the group, she mates with their mates so that these males behave as if they are the sires of the dominant female's young. Hence, depending on size-determined metabolic investments and needs, social systems of canids can vary from

polygyny to polyandry and sometimes use the services of juvenile or adult nonbreeders to help rear offspring.

## B. Kinship and Demography

Although the abundance and distribution of key ecological resources are important in determining the particular pattern of sociality exhibited by a population, other factors such as kinship and demography also play significant roles. Ever since W. D. Hamilton formulated the concepts of "inclusive fitness" and "kin selection," the magnitude of the costs and benefits associated with particular social behaviors, and that ultimately determine which strategy is best, had to be adjusted by degree of relatedness between social partners. Altruistic or cooperative behavior between relatives should be favored whenever  $\text{Benefits} > \text{Costs} * r$  where  $r$  is the degree of relatedness. For both parents and offspring and among full siblings,  $r = \frac{1}{2}$ ; for grandparents and grand-offspring and among half-siblings,  $r = \frac{1}{4}$ , and among first cousins,  $r = \frac{1}{8}$ . Hence, the stronger the degree of relatedness among relatives, the more likely altruists are to enhance the reproductive opportunities of kin while incurring costs associated with diminished personal reproduction. Thus in the examples presented here, it is not surprising to find that the coalitions that form among lionesses when protecting kills and among male lions when protecting mating opportunities with females are formed most often among full siblings; nor is it surprising that the helpers jackals recruit to rear additional offspring are themselves the full siblings of the offspring being raised. In general, strong kinship lowers the threshold for the appearance of altruistic and cooperative behavior and may substantially affect the costs of living in groups.

But as both these cases illustrate, high population density and the intensified competition it engenders for finding suitable territories with sufficient food and habitable burrows is the factor ultimately responsible for favoring the establishment of coalitions or the recruitment of helpers. Thus demographic factors, such as population density as well as sex ratio and age structure, that result from differences in phenotype-specific vital rates also shape patterns of social organization. And since these features of populations are often altered by human activities, understanding how they shape, and are shaped by, patterns of sociality is essential if conservation assessment and planning is to be effective.

Hypothetically, if mortality, for example, were age specific and higher for prereproductive females than males, then high breeding sex ratios (males/females)

would result and mating relationships would generally become more polygynous. If the sex-specific patterns of mortality were reversed, however, then polyandry would become more common. Since some of these mortality concerns were responsible for the variation in canid social structure described earlier, these mortality schedules can have important consequences. Similarly, if mortality rates were size specific and happened to be greater for larger males rather than smaller ones, then discrete size polymorphisms could arise in populations. This appears to be the case regarding the maintenance of so-called alternative male mating strategies. Often the typical strategy adopted by older and larger males of defending harems or resources yields the most reproductive gains but it often incurs the highest costs as well. Because displaying, fighting, attracting the attention of predators, and delaying reproduction while growing are all costly activities, males adopting less successful but also less costly tactics can also flourish.

The maintenance of such alternative mating patterns is common among many species of insects, fish, amphibians, birds, and mammals. For example, in bluegill sunfish (*Lepomis macrochirus*) males typically defend nest sites where they display, attract females with which to mate, and then fertilize and guard the eggs they lay. Since only the largest males have the ability to defend such nest sites, they must delay breeding in this fashion often for more than seven years. As a result, smaller and younger males have evolved various cuckolding strategies that may in fact be equally successful evolutionarily. In one, the so-called sneak begins breeding at two years of age. Although very small, such sneaks are virtually all testes and because of their inconspicuousness can dive from the surface just as a mating pair release sperm and eggs. By exuding large volumes of sperm, some make it to the eggs and fertilize a few. In the other, males delay breeding for as long as do females. By being the same size and color as females, these males join the mating pair and apparently fool the displaying male into thinking that he is courting two females. Then as the original pair releases their gametes, he does too and thus fertilizes some of the females' eggs. For these two strategies to be equally successful alternatives, the costs and benefits of each must vary inversely with frequency. Although they sometimes do, as in the case of the bluegill sunfish, in other species they do not.

A variant on this theme is associated with sex change. For many species, especially among the fishes, individuals begin life as one sex and end life as another. In bluehead wrasse (*Thalassoma bifasciatum*), for example, most individuals begin reproducing as females while

residing with one male. If he disappears, then the largest female changes sex and becomes the harem tending male. Alternatively, in anemonefish (*Amphiprion* spp.), some individuals change from male to female. In either protandrous (male first) or protogynous (female first) species, the sex that is last is the one whose reproductive success is most influenced by body size, and this ultimately depends on the nature of the social system.

Clearly, a variety of environmental features influence the patterns of sociality that populations of animals develop. In many cases these patterns are flexible and species can vary in the system of social organization they exhibit depending on environmental conditions. Thus although female burros and asses typically live in transitory groups whose membership changes, when populations move from arid to mesic areas, social relationships can change. As was found on an island off the coast of Georgia, with food and water both more abundant and less separated, females with differing needs can and do coalesce into permanent groups. Males, which in arid areas are forced to establish territories along routes to and from water, respond by defending these groups much like males of horses, their close kin, and harem-like societies emerge.

### III. FROM SOCIAL ORGANIZATION TO ECOLOGICAL IMPACTS

Despite the fact that some species exhibit social flexibility and that there exists significant "environmental determinism" in the development of patterns of sociality, knowledge is only now emerging about how changes in social systems impact important vital rates, alter interspecific competitive abilities, and shape a population's growth rate and genetic structure. Never before have the social systems of so many species been forced to respond to human activities, most of which lead to reductions in population size, through overharvesting, fragmentation of landscapes or habitats, and changes in the earth's climate. How are we able to predict which species will respond and how will a species' response impact its long-term growth and the health of the ecosystem in which it resides? When we intervene will we do so with a sufficient understanding of what the consequences of changing social behavior and social systems are likely to be? For example, will we know when a species switches from a monogamous to a polygynous social system and whether its growth rate or genetic diversity will increase or decrease? Will we

know whether it will be more or less able to withstand selective harvesting or habitat fragmentation? Such consequences of differing patterns of sociality must be understood before endangered species or their habitats can be protected.

### A. Consequences of Social Change

Many examples are now appearing of human induced changes in species' social systems. One population of feral horses inhabiting a barrier island off the east coast of the United States has been impacted twice by human activities and both times major changes to social behavior and social organization resulted in large-scale changes in the population's vital rates. The first instance occurred when dredging of surrounding ship channels altered currents and sediment deposition around the island. Before the emergence of hundreds of hectares of a new continuous sward of grassland, the island's horses exhibited two types of social organization. Where the vegetation was abundant and evenly distributed, females formed permanent membership groups and associated with a single male. Such harem groups were stable and males protected their females from harassment by intruders and rarely herded their own females. Where the preferred high-quality vegetation was broken up into patches of variable size by extensive ridges of sand dunes, females were not able to aggregate into permanent membership groups. As a result, males wandered in search of reproductively receptive females and, when doing so, harassed females and limited their ability to forage. Not surprisingly, the body condition and reproductive success of the harassed females was much lower than that of females bonded to males. After the emergence of the new sward of grassland in the region where females lived in the fission-fusion type of society, females were able to aggregate and males were able to establish harems and the growth rate of the entire population increased markedly. Thus when the abundance and distribution of key ecological resources alter social systems so that they more closely resemble a species' typical system, vital rates and the overall health of the population improve.

When the perturbation moves a population away from its normal pattern, as happened during the feral horse population's second brush with human activity, vital rates decline. As the horse population approached its carrying capacity, population control measures were instituted. During the initial round of management actions, over 85% of the harem stallions were removed from the island. The resulting social disruptions were massive; many females were separated from their males

and young, inexperienced bachelor males took over. Extremely high levels of harassment led to low reproductive rates despite the fact that overall density had also been reduced and food supplies were expanding. As these two disruptions illustrate, human activities that alter existing patterns of social relationships dramatically alter reproductive rates.

Similar outcomes occurred when large-scale El Niño induced climatic changes resulted in major adjustments to time and activity budgets of Alaskan red foxes (*Canis aureus*). Before the 1982–1984 El Niño, many of the foxes on an island in the Bering Sea bred polygynously and produced litters of sizes equivalent to, and often greater than, those of monogamous pairs. After the El Niño and the reproductive failure of the large seabirds, the foxes shifted their diet to smaller, less abundant, and harder to catch prey. Dietary shortages were common, fewer foxes bred and polygyny disappeared. Moreover, the litter sizes of these monogamous pairs were smaller as well. Clearly, changes in social behavior in response to altered environmental conditions enabled some individuals to make the best of a bad situation. Overall, however, the health of the population suffered.

Major changes in the breeding patterns of elephants (*Loxodonta africana*) could result if climate changes alter the patterning of grasslands in East Africa. Ordinarily group sizes and compositions change seasonally in response to changing abundances of vegetation. After the rains, when grasses grow rapidly on the extensive upland plains, small family groups of elephants aggregate into large matrilineal assemblages. With the flush of new vegetation many come into estrus and become reproductively active. At this time only the most dominant bulls come into musth, a heightened sexual and aggressive state. By aggregating, females incite male-male competition thus ensuring that they mate only with the best males. During the dry season, however, after the grasses on the plains stop growing and have been consumed by elephants and other ungulates, the elephants retreat to the swamps where other grasses and browse remain. The patchy nature of the habitat, however, prevents large groups of females from remaining together and the huge herds fission into smaller family units. In addition, few females remain to be mated and the dominant bulls go out of musth. Subordinates become sexually active at this time, but reproductive opportunities are limited. Thus, under a normal environmental regime two evolutionary consequences result: most males do not mate, but those that do are the most fit; and because genetic effective population size is affected by the number of males relative to the number of females mating, the effective population size

of elephants is much smaller than the census population size. If global warming increases the duration and intensity of dry seasons, then selection for the best males will be relaxed but the effective population size of the population will increase, provided that elephants can sustain their high metabolic levels and maintain their high fertility and survival rates. With global changes in climate appearing in many different habitats, other examples of social readjustments that either change a species' evolutionary potential or that act as demographic shock absorbers in the short run, but are unlikely to provide compensatory relief in the long run, are likely to become more common.

## B. Consequences of Demographic Change

Many demographic changes leave their mark by altering critical aspects of social behavior or by disrupting the development of important social relationships. As the elephant example illustrates, changing environmental conditions can change operational sex ratios thus altering a population's ability to maintain genetic diversity. But by changing sex ratios in other ways, humans can put populations at risk by making it difficult for them to grow in size. In lions, for example, trophy hunting, if it removed pride defending males and nomads in proportion to their abundances, would not severely affect population growth and effective population sizes would be maintained at normal levels. But if such hunting focused on pride males, then increased turnover would foster increased infanticide by take over males. While such diversification of the gene pool might increase effective population sizes, it would certainly lower population growth rates because infant survival, which is already low, would plummet. Much clearly depends on whether or not the population is polygynous or monogamous and whether the perturbation will accentuate or reverse the pattern. Large-scale climate changes could reverse and ameliorate the normal pattern as is likely to be the case in elephants, but selective hunting or poaching, as in the case of lions, could exacerbate an already critical situation.

Selective poaching could even make it difficult for populations to recover once the poaching has been eliminated. Since hunting elephants for ivory meant that poachers sought the individuals with the largest tusks first, male numbers were reduced to dangerously low levels before large tusked females and smaller males were hunted. Because females prefer to mate with older males, lowered sex ratios and distorted age structures could make it difficult for all females to mate. As a

result, population growth rates could remain low for historically heavily poached populations.

Harvesting in fish might be accelerating already rapid population declines because of disruptions to normal social interactions. When harvesting is size selective and reduces the number of large females in a population, fecundity might be disproportionately reduced since ovary volume scales allometrically with linear body size dimensions; larger females have disproportionately larger ovaries and high fecundity. And as sex ratios increase, male harassment of the remaining females may further reduce recruitment and population growth rate. When such size selective harvesting removes more males than females, sex ratios are reduced and females may become less choosy and more aggressive when selecting mates. While such changes in the intensity of sexual selection might not alter population growth rates, they might alter the genetic diversity of the population. Yet if males provide the majority of parental care and large males are removed from the population as if often the case in sports fisheries, then recruitment will be markedly reduced as unguarded eggs are cannibalized.

The implications of overzealous size-selective harvesting in sex-changing fish or in fish that exhibit alternative male mating behaviors appear to be equally severe. For species such as anemonefish in which the largest males change to females, removal of the largest females will force males to change sex at ever smaller sizes, thus producing fewer eggs. Population growth rates will be curtailed and the species will find itself at risk all because of overzealous aquarium traders.

Migratory Atlantic salmon (*Salmo salar*) provide perhaps the clearest example of where human activities are changing the balance of male mating strategies within a population and hence the patterns of sociality. Atlantic salmon typically are born in fresh water and develop for 1 to 2 years before smolting and heading to sea to grow and fatten by feasting on a rich supply of marine invertebrates. Once they attain a certain size, they become sexually mature and return to rivers. There they travel long distances upstream until they reach clear and cool breeding grounds. Some individuals, however, never head to the sea. Instead, they remain in their natal streams and mature sexually at young ages and at small sizes. Such individuals are called parr and they never go through the smolting process that adapts them to a marine lifestyle. Under pristine environmental conditions, the fraction of the population that becomes parr is small since the reproductive gains of such a strategy are low. When competing for mates with larger more aggressive males, parr fare poorly. What matings

they obtain are derived by “sneaking” among a mating pair and releasing milt at just the right time. Such events are rare and the mixing of milt is poor so such “sneak” matings result in few young being sired. But the survival prospects of parr are high since they don’t incur the risks of going to sea and, moreover, they begin breeding at a very early age. Thus over a lifetime, reproductive success is moderate. But as human fishing increases and the netting of the older larger salmon intensifies, the *relative* lifetime reproductive success of parr is improving. Since the costs of migrating to sea and back again have increased dramatically, the long life span of parr give them a relative advantage. And given that competition with the larger males for mates is also being reduced, the chances of parr securing matings are also improving. Thus it is not surprising that the composition of the population is changing as parr increase markedly in abundance. The impact on the long-term stability of the population is unclear. But the long-term impact on the balancing of mating morphs and sexual relationships is.

### C. Consequences of Inappropriate Interventions

When humans intervene and develop management and conservation plans they sometimes do so without accounting for important aspects of social behavior. As a result some disastrous consequences have ensued.

Ignorance about the mating system of sperm whales (*Physeter macrocephalus*) has led to the implementation of harvesting plans that have almost led to their extinction. By using data from previous harvests in which the counts of males were much fewer than those of females, sperm whales were thought to exhibit a harem breeding system. Such a conclusion could only have been derived by assuming that sperm whales lived in permanent, closed membership groups. By making this assumption, the International Whaling Commission concluded that most males sighted would be superfluous thus disproportionate hunting of males would not limit the growth rate of the population; most of the males caught would not be necessary for fertilizing females.

Unfortunately, the social relationships of sperm whales are very different from those assumed. Females are the core of the society and do appear to live in permanent membership groups. But these groups often merge when diving for fish and divide labor between fishing and tending the young that cannot dive deeply. Males are forced to leave their natal group when reaching sexual maturity, but they cannot accompany the breeding associations to the tropics. Instead they remain

at the higher latitudes foraging in the cooler more productive waters. Thus when males are hunted on the breeding grounds it is breeders and prereproductives that are taken. With breeding males severely reduced in abundance and the younger, subadult upstarts located thousands of kilometers away, many females are going unmated. As a result, the population is failing to recover and it will be years before the next generation of males is ready to start the population, already handicapped by such a low recruitment potential, on the road to recovery. Knowledge about sperm whale social relationships could have prevented the mistaken overharvesting of mature males.

Another species in which ignorance about important features of social behavior is problematic is the black rhinoceros (*Diceros bicornis*). During the past 25 years, numbers have declined from 65,000 to fewer than 2500 because demand for their horns is so great. In an attempt at making rhinos less desirable, some nations have implemented a strategy of dehorning. Other nations have opted to translocate rhinos to extremely well protected areas. Unfortunately, horns, and thus the value of rhinos, regrow quickly. But what is more troubling about the dehorning treatment is that it appears to disrupt effective maternal antipredator behavior. Although dehorned rhinos were no more likely to flee from predators than intact rhinos, the disproportionate disappearance of offspring being reared by dehorned mothers as opposed to intact mothers in areas with large numbers of lions and spotted hyenas suggests that horns play a vital parental and protective function. Dehorning, although initially thought of a cure for the disappearance of adults via poaching, became a contributing factor to the disappearance of young via predation. Although dehorning might enhance adult survival in the short run, it would limit a population’s growth potential in the long run.

A third example where ignorance hindered, but did not harm, a conservation program involved the reintroduction of Asiatic wild asses (*Equus hemionus*) to habitats within its historical range. A goal of the Israeli government is to repopulate Judea and Samaria with biblical animals. Since the Palestinian race of the wild ass was extirpated by the Ottoman Turks at the beginning of the twentieth century, the onager was a prime candidate for translocation. The first reintroduction took place in 1982 with subsequent additions throughout the 1980s and increased the number of breeding females to 14. By the mid-1990s, however, the population had hardly grown and the number of breeding females totaled 16. What was not known at the time was that breeding success is bolstered by being reared

in the wild and that onagers could facultatively adjust the sex ratio of the offspring they produced. In the Negev Desert, free-ranging onagers gave birth disproportionately to sons.

Trivers and Willard were the first to suggest that differences in the ability to invest in the successful rearing of offspring should lead to individual differences in the primary sex ratios of offspring. They argued that females with sufficient resources should invest in offspring of the sex with the higher variance in reproductive success. By producing well-endowed offspring of this sex, mothers would increase the number of grand-offspring they were likely to have. In polygynous species like the onager, males are usually the sex with the greatest variance. Since onager females compete more on the basis of resource exploitation, or utilization efficiency, rather than via direct conflicts settled by social status, sex biases in offspring production were not expected. However, because age and experience affect utilization efficiency, differences in bodily condition and ability to invest in offspring were expected to exist among females in this onager population. Thus it was heartening to find that middle-aged females—those in the best physical condition—gave birth to more sons than daughters. Conversely, those breeding for the first or second time gave birth to daughters as did older females nearing the end of their reproductive lives.

The strategy the Israelis employed of translocating middle-aged females to the desert was sensible in economic terms since high risks were attached to releasing very young females and low future expectations were associated with releasing older females. But had the

Israelis released old females with yearling daughters they would have quickly accelerated the growth of the population. At the time, an understanding of how environments shape patterns of onager social behavior and the impacts that these behaviors would have on population dynamics was unknown. By understanding the relationships between environments and social behavior and between social organization and population processes, we should be in a better position to understand the problems endangered species are likely to face and what interventions to protect them are likely to be effective.
